ABSTRACT

Near-infrared imaging and spectroscopic observations of the extremely red object Cl 0939+4713B ($R-K \sim 7$ mag) have been obtained with the Near Infrared Camera on the Keck I Telescope of the W. M. Keck Observatory. The imaging shows a slightly elongated structure, while the spectroscopy shows a continuum break that allows us to determine a redshift of $z = 1.58^{+0.01}_{-0.03}$ for this system. The fits of a range of models to the infrared spectrum suggest that it is predominantly an old ($> 10^9$ yr) stellar system that suffers little extinction, while the measured R and I magnitudes suggest an age of $\sim 3 \times 10^8$ yr. The limit on the equivalent width of any emission line in the infrared spectrum suggests that Cl 0939+4713B is not an actively star-forming galaxy. This system, though similar in $R-K$ color to the object HR 10 (also known as J1645+46), is much different in morphology and emission-line strengths, demonstrating the heterogeneity of extremely red extragalactic objects selected on the basis of large $R-K$ values.

Key words: galaxies: distances and redshifts — galaxies: evolution

1. INTRODUCTION

Over the last decade, several groups (Elston, Rieke, & Rieke 1988; Elston, Rieke, & Rieke 1989; Eisenhardt & Dickinson 1992; McCarthy, Persson, & West 1992; Persson et al. 1993; Hu & Ridgway 1994; Dey, Spinrad, & Dickinson 1995; Djorgovski et al. 1995; Barger et al. 1999) have reported finding a class of extremely red objects (EROs), with $R-K > 6$ mag, that are reasonably bright ($K < 19$ mag) and relatively frequent (surface densities ~ 0.01 arcmin⁻² at $K < 18$ mag; Hu & Ridgway 1994; Thompson et al. 1999).

The earliest studies suggested that these systems might be at extremely high redshifts (Elston et al. 1988), but this has not been borne out. Recent work has shown that these systems have spectral energy distributions (SEDs) in the visible and near-infrared consistent with elliptical galaxies or very dusty galaxies at $z > 1$ (Persson et al. 1993; Hu & Ridgway 1994; Trentham, Kormendy, & Sanders 1999). Recently, Graham & Dey (1996) have reported imaging and spectroscopy of one of the brightest of these red objects, HR 10, discovered by Hu & Ridgway 1994. Graham & Dey (1996) report the detection of a spectral feature at $1.6 \mu\text{m}$, which they associate with $H\alpha$ at a redshift of $z = 1.44$. They further suggest that the morphology of this system is consistent with an interacting galaxy system, which indicates that this is a dusty, starburst galaxy or an active galactic nucleus

(AGN). Dey et al. (1999) confirm the redshift of HR 10 with the detection of $[\text{O II}] \lambda 3727$. Both Dey et al. (1999) and Cimatti et al. (1998) report the detection of HR 10 at submillimeter wavelengths, supporting the suggestion that it is a dusty, interacting galaxy. Smail et al. (1999) have also suggested that up to half of the EROs could be associated with submillimeter sources detected in Submillimetre Common-User Bolometer Array surveys.

Understanding the nature of EROs, or even whether they represent a homogeneous class, is important for several reasons. If these are indeed starburst/AGN systems at $z > 1$, they could be the high-redshift analogs of the ultraluminous infrared galaxies seen locally (e.g., Soifer et al. 1984; Sanders et al. 1988; Trentham, Kormendy, & Sanders 1999). If powered by hot, young stars, such systems would have star formation rates greater than those for most of the young galaxies at $z \geq 3$ found by Steidel et al. (1996). Alternatively, if they are distant, passively evolving, elliptical galaxies, then the determination of their ages might well place significant constraints on the formation epoch of massive galaxies.

As part of a program to study the nature of these objects, we have undertaken near-infrared spectroscopy of one of the brightest of these objects on the Keck I Telescope of the W. M. Keck Observatory. In this paper, we report spectroscopy and imaging for Cl 0939+4713B, an object serendipitously found by Persson et al. (1993) in the infrared in the field of a rich cluster of galaxies at $z = 0.41$ (Dressler & Gunn 1992) and referred to by them as $9\alpha\beta$ B. It is non-stellar and located $\simeq 4''$ southwest of galaxy 174 in the cluster (Dressler & Gunn 1992). Persson et al. (1993) reported a K magnitude of 18.3 and $r-K > 7.4$ mag. Assuming a passively evolving stellar population, Persson et al. (1993) estimated a redshift of $z = 1.8$ for Cl 0939+4713B and an age of 3×10^9 yr by fitting their photometry at r , i , J , H , and K to the models of Bruzual (1985). The grism observations reported here allow us to search for emission lines such as those found in the spectrum of HR 10, as well as to directly measure any continuum in the spectrum. Throughout this paper, we adopt $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and $q_0 = 0.5$ (and $\Lambda = 0$).

2. OBSERVATIONS AND DATA REDUCTION

Photometric and grism observations of Cl 0939+4713B were made on 1997 March 31, using the Near Infrared Camera (NIRC; Matthews & Soifer 1994) on the Keck I Telescope. The array has 256×256 pixels and a scale of $0''.15 \text{ pixel}^{-1}$. Photometry at J ($1.27 \mu\text{m}$), H ($1.65 \mu\text{m}$), and K ($2.2 \mu\text{m}$) was obtained in seeing with FWHM $\sim 0''.4$; the data were calibrated by reference to the calibration stars of Persson et al. (1998).

The final K -band image shown in Figure 1 was created by combining 15 individual frames of 12 s each, taken both before and after the spectral data. The telescope was moved $5''$ – $10''$ between individual frames, and sky and flat-field images were constructed from the data themselves, after masking out bright sources in the field. Although there are no obvious point sources on the image of Cl 0939+4713B itself, the seeing at the time of the observations was estimated to have FWHM $\simeq 0''.4$, measured from standard stars observed immediately before the data were taken.

Low-resolution spectra that span the range 1 – $2.4 \mu\text{m}$ were obtained in two wavelength settings. For the wavelength range 1.0 – $1.6 \mu\text{m}$, 4500 s of observations were made, while 7800 s of observations were made for the range 1.6 – $2.4 \mu\text{m}$; individual observations were ~ 300 s in duration. The slit was 4.5 pixels ($\sim 0''.68$) wide and aligned essentially north-south such that the bright galaxy to the south was included in most spectra. The object was moved to five positions along the slit for successive integrations.

The data were processed in a conventional manner. The spectra were corrected for atmospheric features by dividing the spectra of Cl 0939+4713B by that of a G6 V star observed on the same night at similar air mass. The spectrum of the G6 V star closely approximates that of a blackbody of temperature 5600 K at the spectral resolution of the

observations and so was assumed to follow the blackbody spectrum. The infrared spectrum and R -band photometry were put on a common absolute scale by integrating the infrared spectra over the appropriate wavelength bands and scaling the spectral flux densities to correspond to the photometry in a $3''$ diameter beam. The infrared data were boxcar-smoothed to 2 pixels, i.e., $\Delta\lambda = 0.0135 \mu\text{m}$, the spectral resolution corresponding to half of the slit width.

In addition to the near-infrared observations, images of Cl 0939+4713B were taken using the Low Resolution Imaging Spectrograph (LRIS; Oke et al. 1995) on the Keck II Telescope. Three 600 s images, slightly offset in pointing location between images, were taken through an R filter in 1998 March. The seeing on the summed image was FWHM $\simeq 0''.9$. Eighteen 200 s images with slight positional offsets were taken in the I filter on 1998 November 1 (see Smail et al. 1999). The night was photometric, and the total integration time was 3600 s; the seeing was $0''.65$ FWHM. The data for both images were reduced using standard techniques. The photometry was calibrated to the standard system of Landolt (1992).

3. RESULTS

The R and K images of Cl 0939+4713B are shown in Figure 1, while Table 1 reports the photometry for the source. The K image shows that Cl 0939+4713B is resolved, having a bright core with a clear elongation in the east-west direction. The K magnitude of Cl 0939+4713B from the Keck imaging is 18.16 ± 0.06 mag in a $3''$ diameter beam. To determine whether this value is affected by the presence of the nearby, brighter galaxy (galaxy 174), the bright galaxy was subtracted from the image by rotating the image by 180° about the center of galaxy 174 and subtracting it from the original image. This successfully eliminated

FIG. 1.—Images of Cl 0939+4713B at R and K , obtained using LRIS on the Keck II Telescope and NIRC on the Keck I Telescope. The field is $36''$ square for both filters, and the scales are identical. North is up and east to the left. Cl 0939+4713B and A are both clearly seen in the K -band image and are visible on the R -band image. The location of Cl 0939+4713B is $9^{\text{h}}42^{\text{m}}56^{\text{s}}.8$ and $+46^{\circ}57'48''$ (J2000.0).

galaxy 174, while preserving the other objects in the image. The *K* magnitude of CI 0939+4713B, measured in the image where galaxy 174 was eliminated, is 18.26 ± 0.10 mag. Our conclusion from this is that the two measurements are consistent within the uncertainties and galaxy 174 does not significantly affect the measurement of CI 0939+4713B at *K* in a 3" diameter beam. The *K* measurement of Persson et al. (1993) is consistent with the value reported here.

The spectrum of CI 0939+4713B, plotted versus observed wavelength from 1.0–2.4 μm , is shown in Figure 2. The flux scale of Figures 2 and 3 is set such that the flux level in the spectrum agrees with the average of the Keck photometry at *J*, *H*, and *K*, as presented in Table 1. Because the spectral standard that was used is not calibrated photometrically, there is no independent calibration of the spectrophotometry. The spectrum is comparatively flat for wavelengths $\lambda > 1.2 \mu\text{m}$ and drops rapidly below this wavelength. There are no strong narrow emission features in the spectrum, and the only strong continuum feature is the apparent change of slope at $1.2 \mu\text{m}$.

In the *R* image, the object is also resolved, with a measured FWHM of $1''.27$. The original *r* magnitude for CI 0939+4713B, reported by Persson et al. (1993), was

FIG. 2.—Spectrum of CI 0939+4713B, plotted as flux density f_λ ($\text{W m}^{-2} \mu\text{m}^{-1}$) vs. observed wavelength (in μm). The hatched zones correspond to the wavelength intervals that have large corrections in the division by the G star caused by low atmospheric transmission.

FIG. 3.—Spectrum of CI 0939+4713B, plotted as $\log [\text{flux/octave } \lambda f_\lambda (\text{W m}^{-2})]$ vs. observed wavelength (in μm), and compared with models of ages 10^7 , 10^8 , 2.9×10^8 , 10^9 , and 10^{10} yr. The infrared data (filled circles) are plotted at the resolution of the spectrum, and the infrared fluxes have been adjusted to be consistent with the near-infrared photometry. The models are for solar metal abundance, and the redshift and reddening corresponding to the values in Table 1. The models proceed from youngest to oldest from top to bottom. The *R* and *I* photometric fluxes are included as filled diamonds. Because of the widths of the bandpasses, these fluxes depend on the assumed object spectrum. For the models shown, the flux per octave ranges from $-17.48 < \log [\lambda f_\lambda (\text{W m}^{-2})] < -17.36$ (*I*) and $-18.27 < \log [\lambda f_\lambda (\text{W m}^{-2})] < -17.94$ (*R*). The values calculated for a Bruzual & Charlot (1993, 1996) model with an age of 2.9×10^8 yr are plotted; the precepts outlined in the explanatory supplement to the *IRAS* catalogs and atlases (Joint *IRAS* Science Team 1989) for color corrections were followed. The effective wavelengths of the band were chosen as 0.61 and $0.81 \mu\text{m}$. The horizontal bars on the *R* and *I* points indicate the full widths at half-peak of the filter and CCD transmission.

$r > 25.7$ mag, based on a nondetection of the source in the *r* image of the field. The Keck *R* image detects the source with a measured magnitude of 25.57 mag in a $1''.3$ diameter beam. The aperture correction to a 3" diameter was determined to be 0.44 mag (with substantial scatter, ~ 0.4 mag) by using objects of similar brightness in the same image. This leads to a total *R* magnitude of $25.13^{+0.5}_{-0.3}$ mag. Uncertainties in the *R* magnitude, in addition to the aperture correction, arise because of the proximity, within $\sim 4''$, of the much brighter galaxy (galaxy 174 in the cluster; see Fig. 1) to the northeast.

The *R* magnitude reported here is somewhat brighter than the original limit, $r > 25.7$ mag, of Persson et al. (1993). The measurement at *R* and limit at *r* are entirely consistent with the transformation between *r* and *R* magnitudes given by Kent (1985). The color derived from the Keck data is $R - K = 7 \pm 0.5$ mag and is dominated by the uncertainty in the *R* magnitude.

There are no galaxies apparent closer than $4''$ to CI 0939+4713B, although CI 0939+4713A, as reported by Persson et al. (1993), is $\sim 7''$ away and has an $r - K$ color of 6.2 mag. The Keck observations give an *R* magnitude of 24.75 mag for CI 0939+4713A, in excellent agreement with the *r* magnitude of 24.7 mag from Persson et al. (1993).

CI 0939+4713B is very clearly resolved in the *I* image, with a magnitude in a 2" diameter beam of $I = 23.26 \pm 0.07$ mag. The aperture correction to a 3" diameter beam is approximately -0.1 mag, yielding an *I* magnitude in a 3" diameter beam of $I = 23.16 \pm 0.15$ mag. The measured *I* magnitude leads to a flux density of a factor of ~ 3 greater than the flux density determined from the *i* magnitude of

Persson et al. (1993). The extended long-wavelength spectral response in the I measurement can account for some, but not all, of this discrepancy.

The LRIS R - and I -band photometry is included in Figure 3 and discussed below.

4. DISCUSSION

The nature of high Galactic latitude EROs is still highly uncertain. Spectral energy distributions of old stellar populations and young, reddened galaxies are consistent with the broadband observations of many of the extremely red objects, and more detailed observations are required to distinguish between these alternatives. In the case of HR 10 (Hu & Ridgway 1994), the detection of emission lines and a submillimeter continuum (Graham & Dey 1996; Cimatti et al. 1998; Dey et al. 1999) convincingly suggest that this is a comparatively “young” galaxy, whose colors are substantially affected by reddening.

The observed $R-K$ color of Cl 0939+4713B places it among the EROs found in field surveys at K (Hu & Ridgway 1994; Cohen et al. 1999; Barger et al. 1999; Thompson et al. 1999). The SED of Figure 3 allows us to place constraints on the redshift, reddening, and evolutionary state of this galaxy. First, we provide a qualitative view, considering two extreme states, a very young galaxy and a very old galaxy, and then introduce galaxy models to deduce quantitative results. We consider the possibility of dust in the nearby galaxy 174 affecting Cl 0939+4713B to be most unlikely. The projected separation of the two objects, ~ 30 kpc at $z = 0.41$, is very large; thus, significant dust would have to be present at a very large distance from the center of that galaxy. Second, the low redshift ($z = 0.41$) of galaxy 174 indicates that any reddening of the observed infrared light in Cl 0939+4713B resulting from the intervening galaxy would be affecting wavelengths that are not substantially different from the observed wavelengths. This would require substantially more dust to produce an observable effect than would be the case if the dust were associated with the (presumably) much higher redshift source Cl 0939+4713B.

If the galaxy is very old, the integrated light is dominated by G and K stars. The apparent break near $1.2 \mu\text{m}$, then, must be the 4000 \AA break. It cannot be the 2800 \AA break, as this would be weaker than the 4000 \AA break, which would then lie at $\sim 1.7 \mu\text{m}$, and there is no sign of this feature in the SED of Figure 3. As described below, we consider the possibility of the break being the result of the Lyman limit to be most unlikely. The redshift is thereby constrained to lie near $z = 2$. The flat continuum observed in the near-infrared is thus the Paschen continuum of G/K stars, and since the observed continuum is not very red itself, the reddening must be small.

If the galaxy is very young, there is no natural strong break in the spectrum of hot stars, except the Lyman limit. We rule out a Lyman-limit break because of the detection of the galaxy at R and I , as well as considerations of plausible luminosities. The break and apparent slope must then be attributed to the effects of reddening. The spectra of local starbursts are smooth (Schmitt et al. 1997), and the reddening is approximately inversely proportional to wavelength; thus, there is no way to reproduce the strong break seen at $1.2 \mu\text{m}$ in the spectrum. In this case, there is no qualitative match to the observed SED with a normal reddening curve for any choice of redshift.

To make this comparison more quantitative, we fitted the observed infrared spectrum with the population synthesis models of Bruzual & Charlot (1993, 1996). Because the data do not have high signal-to-noise ratios, there is limited information that can be derived from model fitting. We fitted instantaneous-burst models of metal abundances $Z = 1 Z_{\odot}$ and $Z = 0.2 Z_{\odot}$ and a range of ages. For each age model, the redshift and reddening (using the reddening law from Gordon & Clayton 1998) were varied to minimize the χ^2 of the fit. The models were fitted only to the near-infrared data, because the R and I data were qualitatively and quantitatively different from the grism data. However, the consistency of the R and I data with the various model fits was checked. The results of the fits are given in Table 2.

The redshift of Cl 0939+4713B, determined in this manner, was comparatively insensitive to the metal abundance, age, and reddening of the model and was established primarily by fitting the drop in observed flux below $1.2 \mu\text{m}$ to the break in the continuum for the model. Formally, the best-fit redshift is consistently around 1.58, although the minimum reduced χ^2 was 2.5 or greater. For a given model, the χ^2 increases substantially at $z < 1.55$ and $z > 1.59$; therefore, we take $1.55 < z < 1.59$, or $z = 1.58^{+0.01}_{-0.03}$, as the result of our fitting. Persson et al. (1993) determined a redshift of $z = 1.8$ for this object, based on fitting their r , i , J , H , and K data to the models of Bruzual (1985). Presumably, the difference between the photometric redshift and that determined here is the result of fitting the 4000 \AA break to the steep slope observed at $\lambda < 1.2 \mu\text{m}$ in the spectroscopic data presented here.

While none of the models provide a statistically acceptable fit, the χ^2 parameter provides a quantitative measure consistent with the visual comparison of the relative goodness of fit of the different models. The older models with solar metal abundances of $Z = 1 Z_{\odot}$ provide better fits to the data than do the models with abundances $Z = 0.2 Z_{\odot}$. The break at $1.2 \mu\text{m}$ is quite strong and best fitted by old stellar populations with solar abundances. Effects that increase the rest-frame flux shortward of rest wavelength $\sim 4000 \text{ \AA}$, such as decreased UV opacity due to lower metallicity or the presence of hot stars, give lower quality fits to the data. The results of the fits to the $Z = 1 Z_{\odot}$ models are shown Figure 3. In Figure 3, we have plotted the best-fit models in the observed frame, with $Z = 1 Z_{\odot}$ for ages of 10^7 , 10^8 , 2.9×10^8 , 10^9 , and 10^{10} yr. For the models with ages of 10^9 and 10^{10} yr, the overall continuum shape, both the slope at $\lambda > 1.2 \mu\text{m}$ and the steep drop to shorter wavelengths, are well fitted with a stellar continuum and modest reddening. In the two younger stellar population

TABLE 2
REDSHIFT AND REDDENING RESULTING FROM THE BEST
FITS OF STELLAR POPULATION MODELS TO THE
INFRARED SPECTRUM OF Cl 0939+4713B

Age (yr)	$1 Z_{\odot}$		$0.2 Z_{\odot}$	
	z	A_v (mag)	z	A_v (mag)
1×10^{10}	1.578	0.1	1.578	0.5
1×10^9	1.582	1.1	1.582	1.4
2.9×10^8	1.588	1.9	1.586	1.9
1×10^8	1.589	2.3	1.582	2.2
1×10^7	1.589	1.8	1.586	2.4

models, the slope of the continuum is set predominantly by the reddening, with the redshift of the Balmer discontinuity adjusted accordingly. The younger age population models produce too much flux in the UV to match both the continuum at $\lambda > 1.2 \mu\text{m}$ and the drop to shorter wavelengths with the smooth reddening curve adopted. The adoption of a different reddening law, such as that of Calzetti (1997), does not modify these conclusions, only the quantitative amount of reddening, since over the wavelength range appropriate to the fit the reddening is a power law of $A_v \sim \lambda^{-1}$, with no unique spectral features.

The models with a single, initial burst of star formation lead to the reddest colors for a given age and thereby lead to the least reddening required to fit a given age stellar population to the observed spectrum. We use the model fits to constrain the formation redshift of Cl 0939+4713B. Because a given age single-burst model is redder than any model with ongoing star formation, this model fit to the data will be the youngest population model consistent with the data. Thus, single-burst models are the most “conservative” fits to the observed spectrum of Figure 3, i.e., the youngest and least reddened, and hence require the lowest formation redshift to fit the data. More complex models, e.g., exponentially decaying burst models, would require star formation to have begun at a larger redshift.

We have included the R and I photometric fluxes in Figure 3. Because of the wide bandpass of the two LRIS filters and the wide range in SEDs between the calibrating stars and the models, care was taken to properly account for the shift in effective wavelength in the different models, i.e., color-correcting the predicted fluxes to the scale set by the standard measurements. Because the range of colors of standards is much less than that of the colors of the ERO, this by necessity was done by calculation, rather than through observations.

The models with $t \geq 10^9$ yr provide better fits to the infrared spectrum than do the younger models. At wavelengths $\leq 1.2 \mu\text{m}$, the older models follow the observed drop in flux, while the younger models do not. The observed R -band flux is consistent with the flux calculated for the 10^9 yr-age models. The models with ages of 10^8 and 10^{10} yr are also acceptable fits to the observed R -band flux. Clearly any single-burst model of age substantially less than 10^8 yr produces significantly more flux than is observed. Including the I , data suggest that the age is less than that suggested by the infrared data. If the model is constrained to pass through the measured R and I fluxes, a model with an age of 2.9×10^8 yr agrees with the infrared data, although the quality of the fit to the infrared data alone is significantly worse than that for the older models.

If $z = 1.58$ for Cl 0939+4713B, the rest-frame absolute B magnitude is $M_B = -22.3$ mag, uncorrected for extinction. Mobasher, Sharples, & Ellis (1993) find $M_B^* \simeq -21.3$ mag for nearby galaxies, such that the luminosity of Cl 0939+4713B is $\simeq 2.5L^*$, a reasonable value for a massive galaxy at this redshift. A significant uncertainty in the luminosity calculation lies in whether Cl 0939+4713B suffers significant magnification because of its presence behind a foreground rich cluster (Dressler & Gunn 1992). While analysis of the magnification resulting from the foreground cluster is beyond the scope of this paper, Smail et al. (1998) suggest a median (flux) magnification factor in the line of sight to rich clusters, including 0939+4713 (but somewhat closer to the center of the cluster than represented by Cl

0939+4713B), of a factor of 2.5. Such a magnification factor would serve to reduce the luminosity of Cl 0939+4713B to a present-day L^* galaxy if there were no significant extinction affecting the observed flux.

As noted above, there is no evidence for emission lines in the spectrum of Cl 0939+4713B. The 3σ limit on the equivalent width of any emission line in the spectrum of Figure 2 is $0.004 \mu\text{m}$. If those portions of the spectrum most affected by the atmosphere and filter cutoffs are removed from the calculation of the standard deviation of the flat continuum, the 3σ equivalent width is decreased to $0.003 \mu\text{m}$. This corresponds to a limit on the equivalent width of any emission line in the rest-frame spectrum from 0.4 to $1.0 \mu\text{m}$ of 12 \AA , if the redshift is given by our fit to the continuum. In particular, at a redshift of 1.55 – 1.60 , the 3σ limit on the rest equivalent width of $H\alpha + [\text{N II}]$ is less than 12 \AA . This limit is more than a factor of 10 lower than the strength of the $H\alpha + [\text{N II}]$ line found in the near-infrared spectrum of HR 10 by Dey et al. (1999). We can immediately say that the emission-line strengths of HR 10 and Cl 0939+4713B are very different if our determination of the redshift of Cl 0939+4713B is correct.

If we assume that the equivalent width of $H\alpha$ is 0.75 times the equivalent width of $H\alpha + [\text{N II}]$ (Kennicutt 1983), this corresponds to a limit of less than 9 \AA on the rest equivalent width of $H\alpha$. We convert the equivalent width to a line luminosity using the observed magnitude and a redshift of $z \simeq 1.6$ (and assuming no magnification); using the relationship between $H\alpha$ luminosity and star formation rate from Kennicutt (1983), this corresponds to a limit of less than $9 M_\odot \text{ yr}^{-1}$ on the star-forming rate of Cl 0939+4713B. In terms of equivalent width, the limit of less than 12 \AA on the equivalent width of $H\alpha + [\text{N II}]$ would place Cl 0939+4713B either among the least active disk galaxies in the local neighborhood (Kennicutt 1983) or as the least active of the infrared selected galaxies (Veilleux et al. 1995). The limit on the $H\alpha$ equivalent width is consistent with continuous star formation lasting for more than 3×10^8 yr, based on the models of Leitherer & Heckman (1995). Thus, there is reasonably compelling evidence that Cl 0939+4713B is not a reddened, young star-forming galaxy, as is the case for HR 10.

Cohen et al. (1999) have suggested that the objects found in the Caltech Faint Galaxy Redshift Survey, with $R-K > 5$ mag, are old systems that are not reddened, consistent with the interpretation of Spinrad et al. (1997). The identification of Cl 0939+4713B as a distant galaxy whose SED is not significantly affected by dust obscuration places it in the category of potentially old galaxies at high redshift.

HR 10 and Cl 0939+4713B have quite similar visual-infrared colors. The detailed properties—i.e., morphology and infrared spectra—of these two systems are very different, leading to very different pictures of the underlying galaxies. This suggests that the objects selected on the basis of having red colors between visual and near-infrared wavelengths (extremely red objects) represent a heterogeneous group, and a much larger sample of these systems must be carefully studied to establish their context in the high-redshift universe.

We thank W. Harrison for assistance with the infrared observations, Rob Ivison, Len Cowie, and Amy Barger for obtaining the I image, Marcin Sawicki for helpful discussions, and Dave Thompson for a careful reading of the

manuscript and several important suggestions. The W. M. Keck Observatory was made possible by the generous financial support of the W. M. Keck Foundation. Infrared astronomy at the California Institute of Technology is sup-

ported by grants from the NSF and NASA. This research has made use of the NASA/IPAC Extragalactic Database, which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with NASA.
